## 1 Introduction

### 1.1 Purpose

The purpose of Smart-Waiter aims to provide a solution that will allow users to order and pay through a mobile application at restaurants.

### 1.2 Description

This opportunity arose from the lack of a universal application in the market that allows users to walk into a restaurant, scan a code to view the menu, and proceed to order and pay through the use of a singular application. Android users will be able to walk into any restaurant that offers our solution, and have the ability to use these services.

### 1.3 Scope

The scope of Smart-Waiter will be limited to providing the user with the following features: viewing the restaurant's menu, creating the user's order, placing the order and paying for their order.

## 2 Overview

### 2.1 Design Principals

#### 2.1.1 Information Hiding

Information hiding is the principle of segregation of design components that are likely to undergo changes as the lifecycle of the application progresses. This way, other key parts of the application will remain unhindered by any possible changes.

#### 2.1.2 Single Responsibility Principal

This principal states every class should have responsibility of a single action within the software architecture. This action shall be encompassed in a class. Doing so will keep each process action separate allowing better organization.

## 2.2 Document Structure

This document structure is based on the general software design document template. This document provides a general overview of purpose, description and scope of Smart Waiter. It then provides a detailed review of system architecture and data design in decomposed components. Lastly, the document provides project schedule.

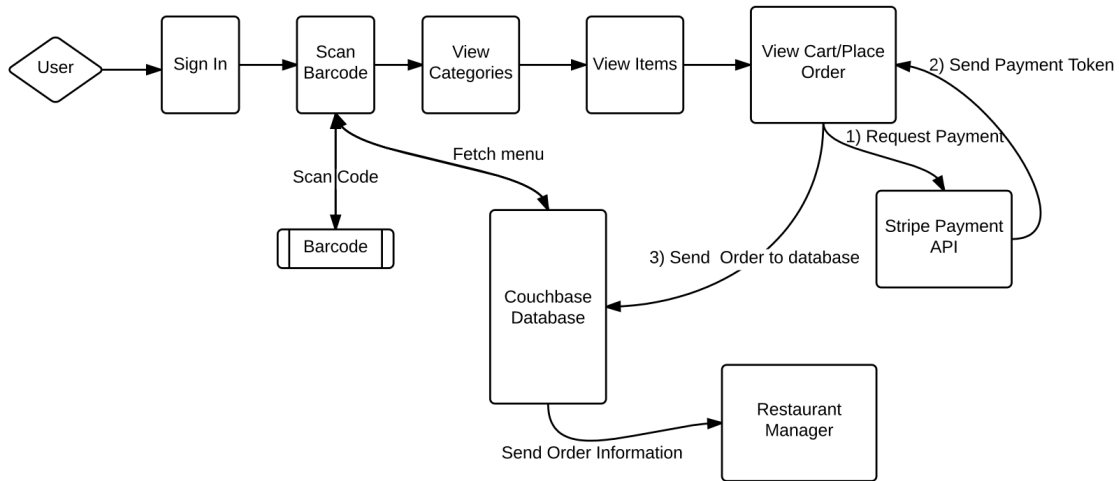

## 2.3 Revision History

Date	Comments
January 11, 2016	first draft.

Table 1: Revision History Table

## 3 Control Flow Diagram

Below is a high level overview of Smart Waiter operation. The operation is decomposed into components which is introduced in this section and will be thoroughly explained in the following sections.

## 4 Module Decomposition

### 4.1 Ordering Class Structure

There are three primary classes used to hold all vital information regarding menu information. These are: MenuCategories, MenuItems and User. In correspondence with single responsibility principal, each class encompasses a single purpose. This purpose and how classes correlate with each other is described below.

#### 4.1.1 MenuCategories Class

This class purpose is to store menu category information of a restaurant menu. This entails category name, picture and a reference to category items. To do so, there are three main variables used within this class to hold this information:

**categoryName:** Stores category name in the form of String

**picURL:** Stores URL of category picture

**categoryItems:** Stores an array of objects that reference MenuItem class

This class is instantiated and called upon when a user successfully scans a barcode. The JSON response acquired from the database is parsed, and information related to menu categories is stored appropriately within this class. The application uses this class to display category information when "Menu Categories" page is spawned (please see section 5.1.1 to view picture).

#### 4.1.2 MenuItem Class

This class purpose is to store menu item information of a restaurant menu. This means, item name, price and description. Three main variables are used within this class to hold this information.

**itemName:** Stores item name

**itemPrice:** Stores item price

**itemDetail:** Stores description of item

Objects of this class are instantiated from the MenuCategories class. By successfully scanning the barcode and parsing the JSON response, MenuItem objects are instantiated and used to save item details. These objects are held within categoryItems list seen in MenuCategories class. This application uses this class to display item information of a category when "Menu Items" page is spawned (please see section 5.1.2 to view picture). These objects are also used in reference to items the user would like to order. This is thoroughly discussed in the proceeding section.

#### 4.1.3 User Class

User class is used to store menu item a user would like to order. For now, there is only one important variable to consider:

**userItem:** an array that stores objects of MenuItem class. This is used to save menu items a user would like to order.

Only one object is instantiated through the life time of this application. This object represents the user cart of menu items he/she would like to order. This object is called upon when a user decides to add an item to their cart. When this occurs, a copy of the MenuItem object is saved within the userItem variables. This way, there is a list maintained to hold all item a user would like to order. When a user confirms and sends their order, the item information is extracted from userItem list, formatted into a JSON request and send back to the database for further processing. Having this class implemented allows extendibility in the future, as all vital information pertaining to a user can be stored within the class (for example, user settings).

## 4.2 Camera Structure

There is one main function related to the Camera structure: `onActivityResult`. The camera is used to read QR codes, which contain the location of where the menu data is stored in relation to the current restaurant. The QR codes are read using an embedded version of the ZXing library. When the application starts, a ZXing specific variable (`IntentIntegrator`) is initialized, when the user clicks the "Scan QR Code" button on the first screen, the Camera is initialized.

### 4.2.1 Design Principles

This component follows the Single Responsibility and the Information Hiding principle.

**Single Responsibility:** The responsibility of this component is to capture and parse QR code data. If this component had to be changed, it would only affect the camera functionality of the application, and not other components like the menu or accounts.

**Information Hiding:** The camera component is separate from every other component of this application. If any changes were to be made to the camera application, it will not affect the other components of the application. However, it is unlikely that there will be any changes applied to this component of the application.

### 4.2.2 `onActivityResult`

This function uses an integrated version of the ZXing library to scan QR codes. After the camera is initialized, the application waits for the user to pass a QR code, this is done by taking a picture of the QR code with the camera. The function `onActivityResult` is called as soon as a QR code is passed. It takes, as input a `requestCode`, `resultCode`, and the current intent:

**`requestCode`:** Used to parse the QR code

**`resultCode`:** Used to parse the QR code

**`intent`:** Gives the current intent, used to parse the QR code

Using the given input, the function parses and gets the contents of the QR code that was passed to the function using the ZXing function `parseActivityResult`. The information stored in the QR code is then saved to a local variable to be used by the other components of the application.

### 4.2.3 Module Decomposition

Module: `onActivityResult`

**Secret:** How the QR code is parsed and read

**Service:** Parses and gets the content of the QR code

## 4.3 Accounts Structure

There are 3 main classes related to the Accounts structure: User, Card, and Stripe. Accounts are used to associate a user identifier for transactions and for storing a user's credit card information securely. Credit card information transfer and storage uses Stripe API. This reduces the burden on the developers, since we can use an established API that follows the restrictions applied by credit card companies, and handles the secure transfer of sensitive information, rather than developing an efficient and secure system ourselves.

### 4.3.1 Design Principles

This component follows the Single Responsibility and the Information Hiding principle.

**Single Responsibility:** The responsibility of this component is to securely store a user's credit card information for use in account transactions. If this component had to be changed, it would only affect the accounts functionality of the application, and not other components like the menu or camera.

**Information Hiding:** The accounts component is separate from every other component of this application. If any changes were to be made to the accounts module, it will not affect the other components of the application.

### 4.3.2 User Class

This class creates a structure for storing a user's account information and general details. The User class has 7 field variables for storing the user's general information. The field variables include: `username`, `password`, `firstName`, `lastName`, `billingAddress`, `postalCode`, `phoneNumber`

**username:** Used as an identifier for the user

**password:** Used for logging into the user's account

**firstName:** First name of the user, used for the billing address

**lastName:** Last name of the user, used for the billing address

**billingAddress:** User's home address, used for billing address

**postalCode:** User's home address, used for billing address

**phoneNumber:** User's phone number, used if we need to get in touch with the user

### 4.3.3 Card Class

This class creates a structure for storing a user's credit card information. The Card class has 4 field variables, which include: cardNumber, cardExpMonth, cardExpYear, cardCVC.

**cardNumber:** Stores the 16 digit credit card number

**cardExpMonth:** Stores the 2 digit expiry month

**cardExpYear:** Stores the 4 digit expiry year

**cardCVC:** Stores the 3 digit CVC code, stored to prevent fraud

### 4.3.4 Stripe

This method is used to securely send credit card information to the Stripe server, the Stripe servers then sends a token that can be used to charge the user's credit card. An instance of the Card class is created using the user's credit card information, and a token is created using the card and the application's Stripe API key. The token is sent to the server, Stripe then returns a token that can be used to charge the user's credit card. The transaction parameters are passed to the charge function, which is then used to accurately charge the user's card. The parameters include: amount, currency, source, and description.

**amount:** An integer value of the amount to be charged to the user's credit card in cents.

**currency:** A string value of the type of currency to be charged, for our application, we will use Canadian dollars (CAD)

**source:** A string value of Stripe token retrieved from the Stripe servers

**description:** A string value containing the description of the charge to the user's credit card.

### 4.3.5 Module Decomposition

Module: chargeParams

**Secret:** How the user's credit card is charged accurately

**Service:** Charges the user's credit card based on the parameters passed.

## 4.4 Backend Architecture

The figure below illustrates how the components mentioned above work together. Specifically, this section will provide details on how Smart waiter utilizes this architecture.

As the following figure illustrates, the backend of the application is designed using Couchbase Lite, Sync Gateway and Couchbase server cluster.

### 4.4.1 Couchbase Lite

Couchbase Lite is a fully functional local database, which runs on the mobile device. This is a local storage system, which is integrated into SmartWaiter application. Similar to the Couchbase Server, Couchbase Lite uses JSON data format, which allows for a flexible data model. Algorithms within SmartWaiter application will be responsible for mapping the JSON data to the application objects. In addition, this solution decouples application data and network connectivity. Thusly, the local data is always available if there is a network connectivity issue or the Couchbase server is down.

### 4.4.2 Sync Gateway

As the figure above illustrates, the sync gateway sits in the middle of the couchbase server and Couchbase Lite running on the users mobile device. This is a key component of the architecture. The sync gateway is responsible for synchronizing the local database with the cloud. Mobile devices only make changes to their local database, and sync gateway takes care of the rest. The gateway will implement authorization for users, which will allow for access control. In addition, channels will be used for access control (details later). Most importantly, the gateway runs Smartwaiter business logic to regulate the synchronization and access control.

### 4.4.3 Couchbase Server Cluster

Couchbase server is the component, which sits in the private cloud along with the sync gateway. As previously described the sync gateway only acts as the manager and administers the traffic between mobile devices and the Couchbase server. The Couchbase server itself is responsible for all data storage in the cloud. The server also uses same JSON data format as Couchbase Lite. For the purpose and scale of the SmartWaiter project, only one server node will be used to hold all data. More importantly, the server will run on a local machine for demonstration purposes.

## 5 Traceability Matrix

Below describes how our decomposed modules relate to requirements specified in SRS

Req.	Modules
R1	Camera Structure
R2	Accounts Structure
R3	Accounts Structure
R6	Ordering Class Structure
R7	Ordering Class Structure
R9	Ordering Class Structure
R13	Accounts Structure
R14	Accounts Structure
R15	Ordering Class Structure
R16	Ordering Class Structure
R18	Ordering Class Structure
R19	Ordering Class Structure

Table 2: Trace Between Requirements and Modules

## 6 Likely Future Changes

### 6.1 Anticipated Changes

**Database:** Consolidation of both databases (for menu items, and orders)

**Database:** Migrating the Couchbase local database to a more powerful machine

**Android:** Add support for Android 6.0

**GUI:** Create a more sophisticated and modern user interface with animations and images

**Accounts:** Switch to self made account system rather than using Facebook API as it may have compatibility issues

## **6.2 Extra Design Features**

**User Preferences:** Make more use of User class by providing the user the ability to store preferences. Eg, food allergies, past meals
